

Introduction to Ecological Assessment of Marine Environments

Dr Aleksandra Zgrundo

Presentation 2

To understand better ideas
behind ecological
assessment we should
also define the concept of
ecological tolerance...

...and to step back
to the beginings of
ecological studies.

In 1840 Justus von Liebig suggested:

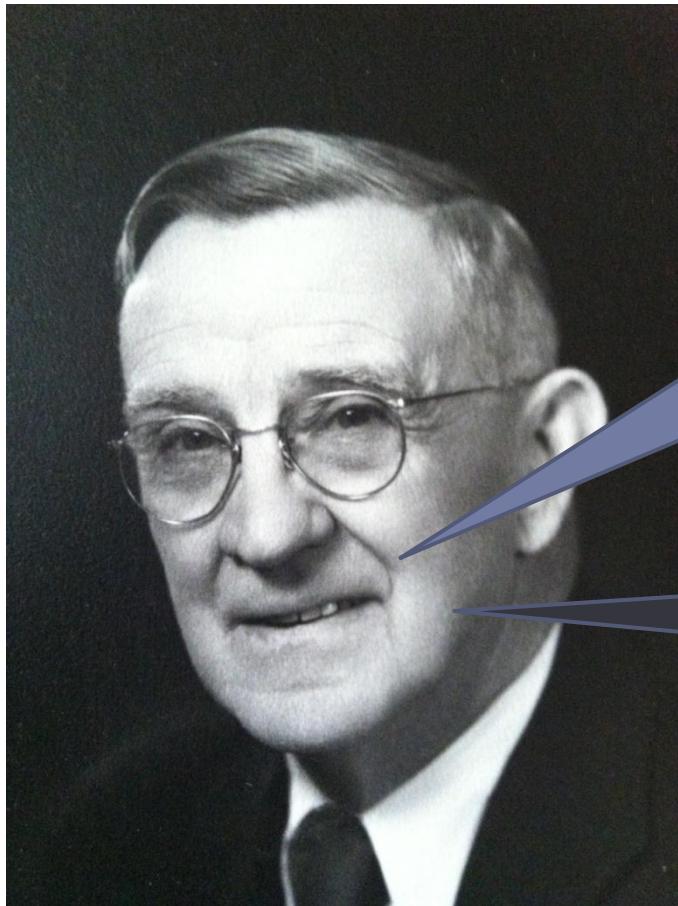

...a growth of a plant depends on that one required nutritional factor that is in the shortest supply.

Under „nutritional factor“ are hidden: water, nitrogen, phosphorus, potassium and other macro- and microelements.

This is known as a „Liebig's Law of the Minimum“

In 1911 Victor Ernest Shelford stated that:

... any excess of environmental factor may reduce an organism's ability to survive, just as the scarcity of a required factor may do.

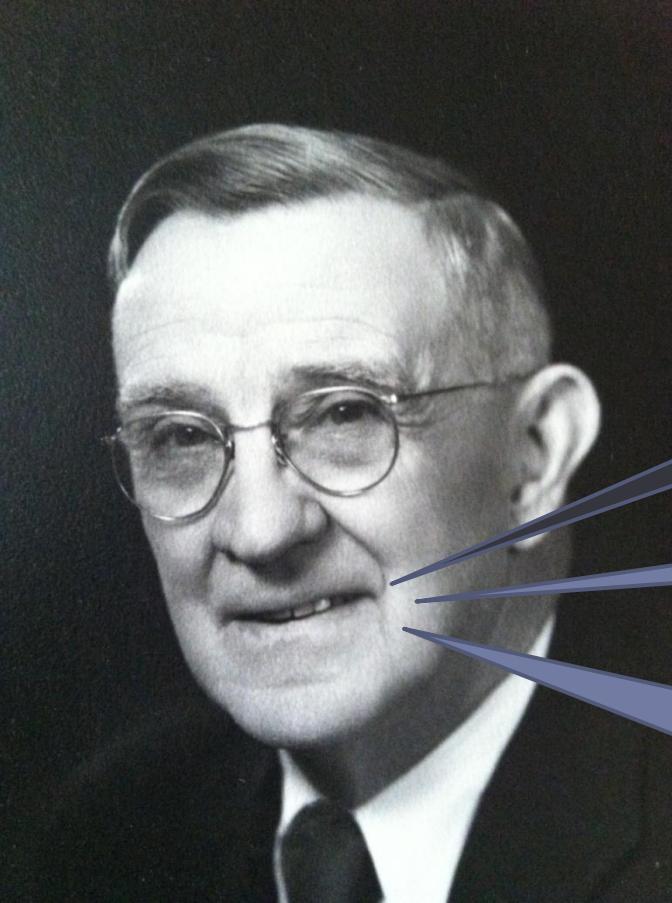

In other words, an organism has a limit of tolerance for any of environmental factors.

This is known as a „Shelford's Law of Tolerance“

Can you give any example
of environmental factor
essential in aquatic
environment?

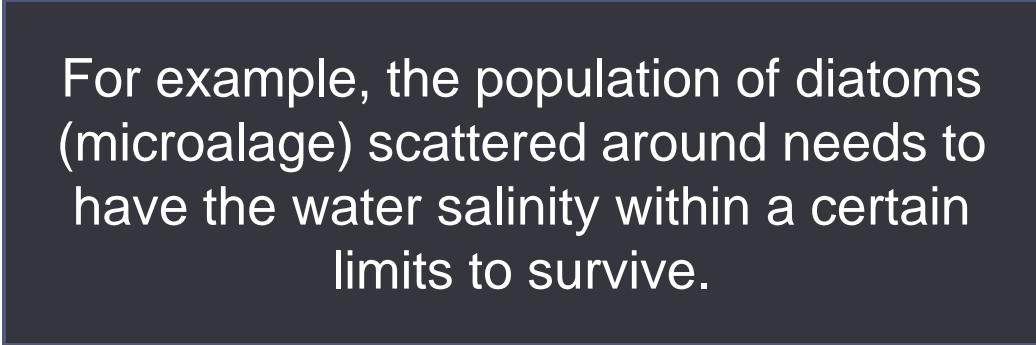

That is right, it can be:
temperature, salinity, pH,
oxygen content, nutrients
content etc.

It is time for the next
question...

Do you know how
range of organisms'
tolerance is described
and illustrated?

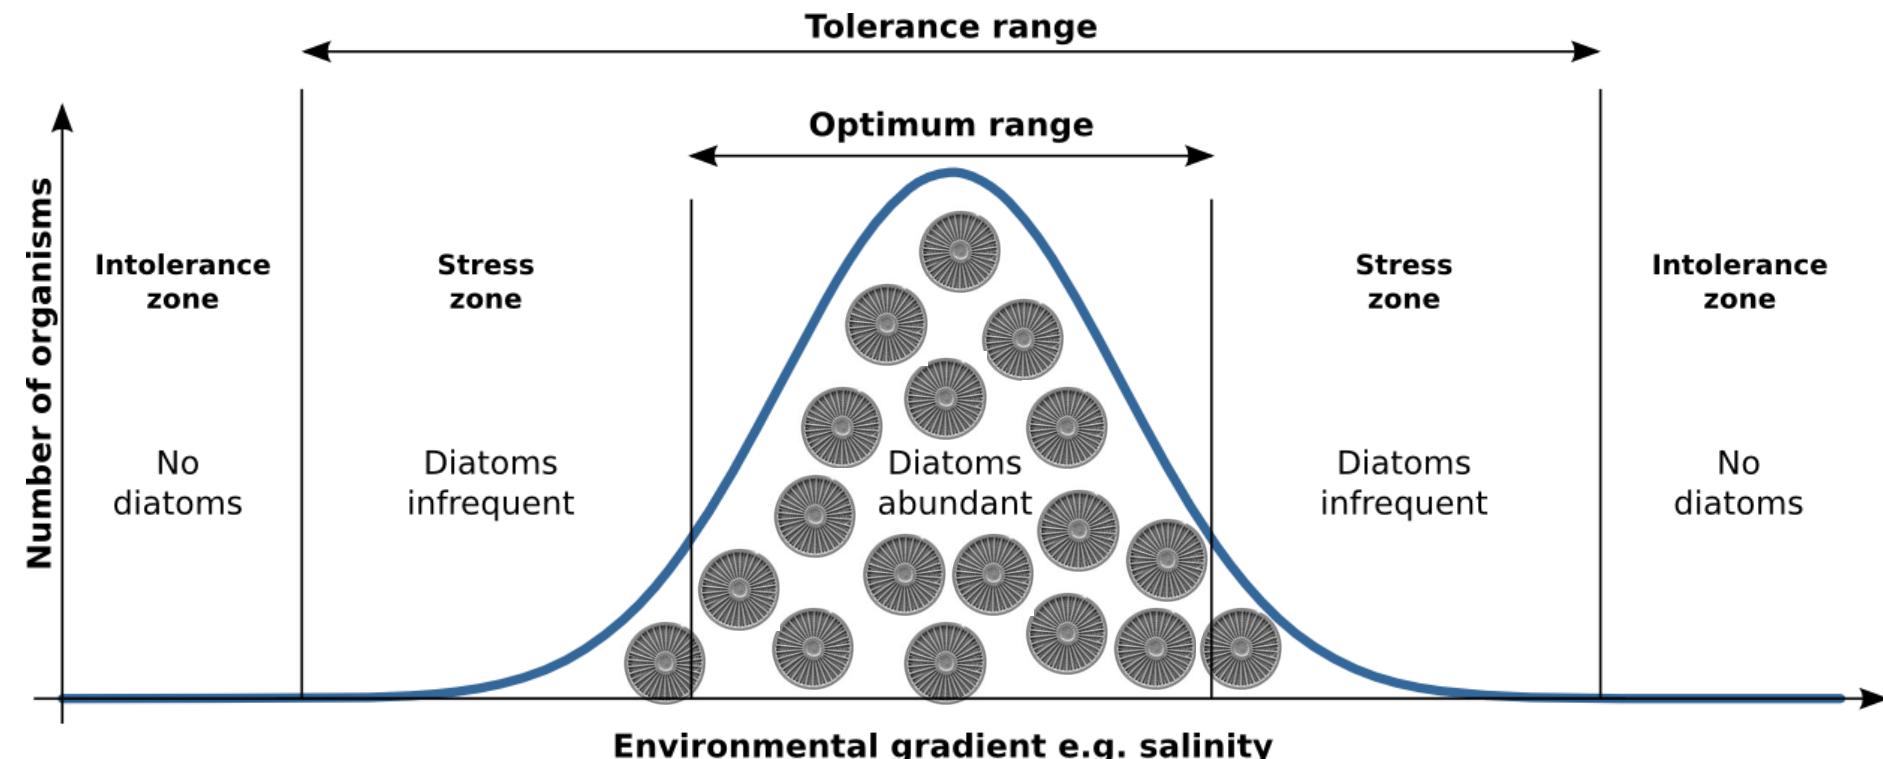

Each species of animal, plant, or any living creature needs a certain set of environmental conditions to survive.

For example, the population of diatoms (microalgae) scattered around needs to have the water salinity within a certain limits to survive.

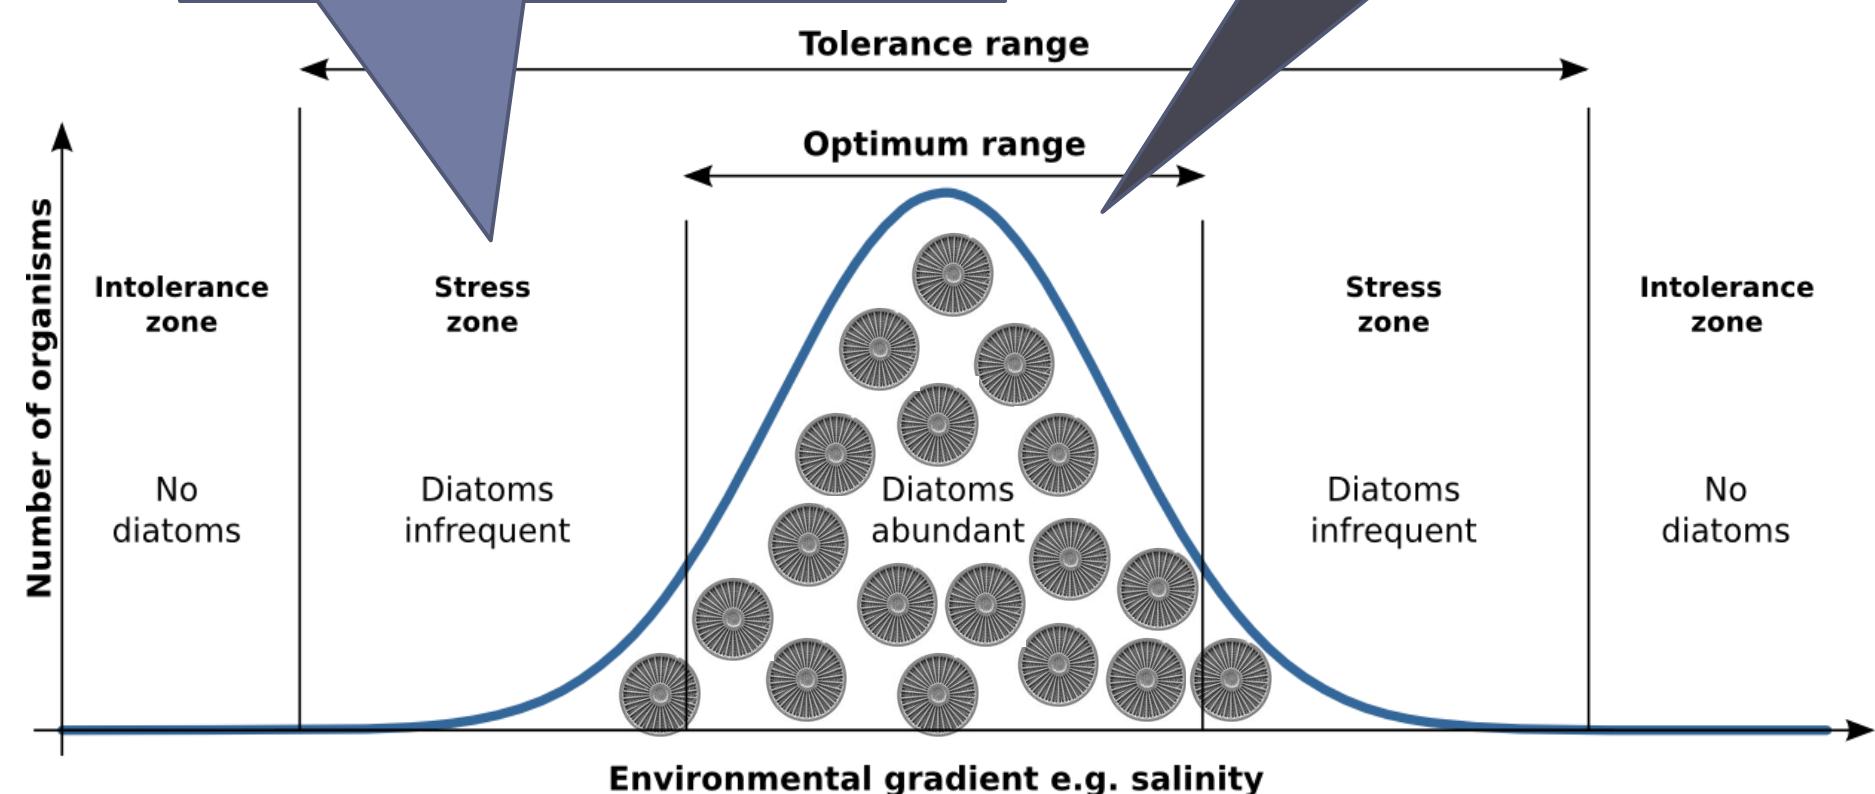

The range of tolerance describes the conditions needed for the population, not the individual. Because, just like people, not every diatom in the population likes exactly the same salinity. And not every diatom can survive extreme salinities at the edge of the range of tolerance.

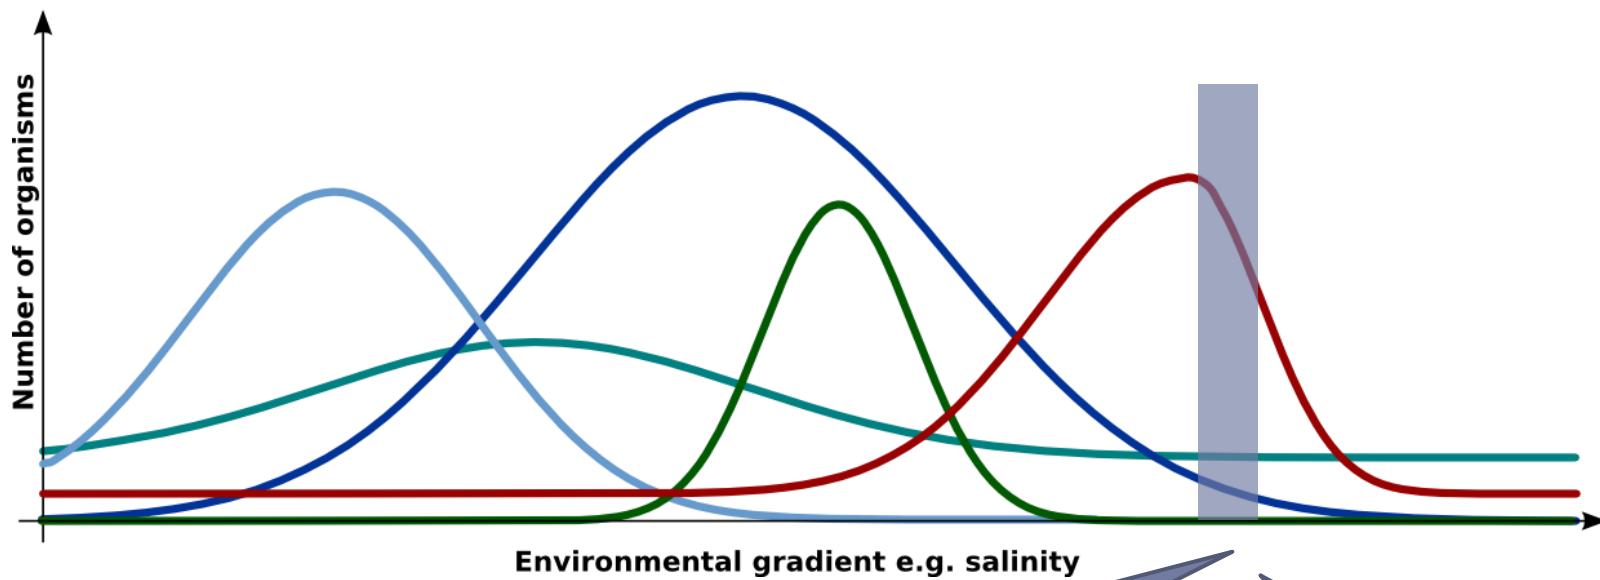

Near the edges of the range of tolerance some organisms can survive but because of physiological stress they do not function properly and reproduce.

In the optimum range many diatoms find the most comfortable salinity. Here, they live and reproduce successfully.

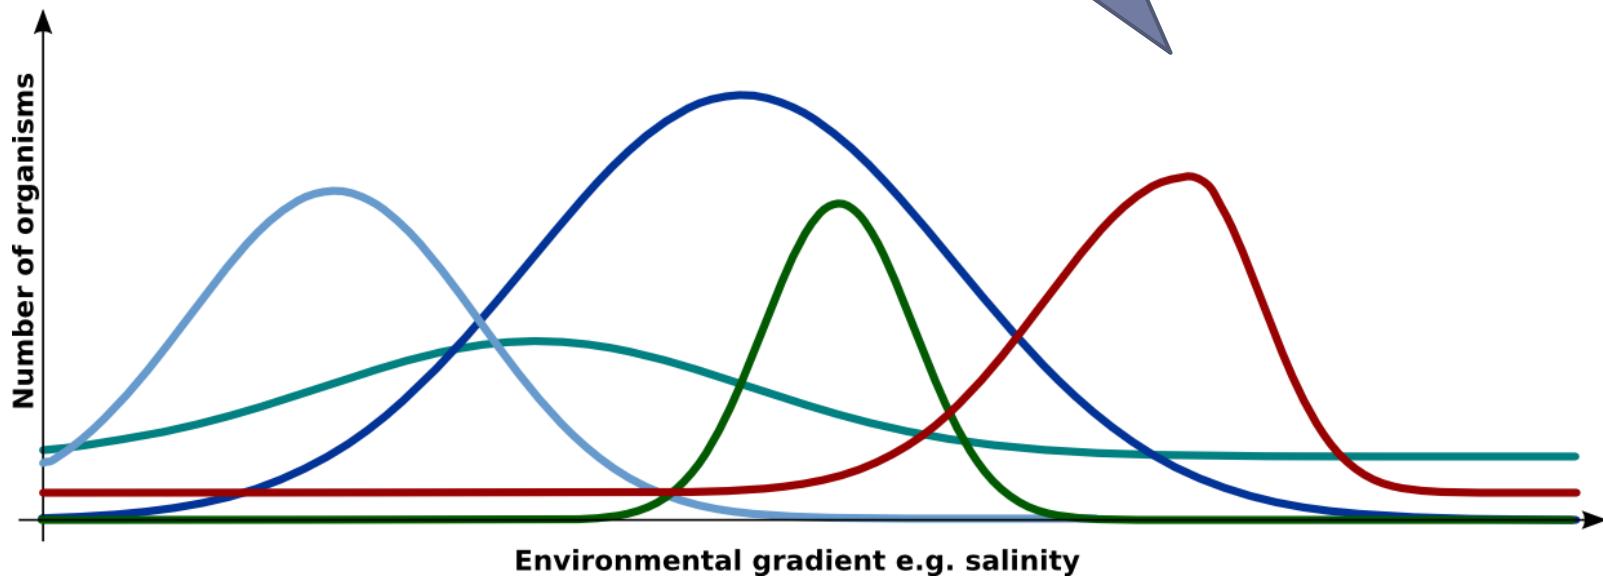

If we put together several species' range in one graph, their tolerance ranges simply overlap and we can observe how the community is formed in the gradient of particular environmental variable.

On the other hand, if we have only information on the abundance of particular species we can predict exactly in what values of gradient they existed in the environment.

This approach is used in the ecological assessment of environments.

On the basis of the low of tolerance can you explain why in biological assessments of environment indicator species were replaced by analysis of whole communities?

A black and white portrait of Aldo Leopold, an elderly man with glasses and a suit, looking slightly to the left.

That is right, community
gives more detailed
information on the state of
the environment than
single species.

The Shelford's Law of
Tolerance lie at the basis of
biological assessments

But the term „tolerance”
used in ecology is
defined differently in
the field of biological
assessments.

Do you know what
I mean?

To understand the difference between the term „tolerance” used in ecology and the use of the term in biological assessments visit a webpage:
http://www.epa.gov/caddis/pecbo_intro4.html

By exploring materials presented at the US Environmental Protection Agency you can learn more about analyzing biological data to infer environmental conditions at a site. In the educational module different methods for computing relations between organisms and environmental variables are described. You can even perform some of the computations on your own!
